In the present work we studied the thermal diffusion behavior of *n*-decane in various alkanes by thermogravitational column (TC) technique and the thermal diffusion forced Rayleigh scattering (TDFRS) method. The investigated lighter alkanes compared to *n*-decane are *n*-pentane, *n*-hexane, *n*-heptane, *n*-octane, and the heavier ones are *n*-tetradecane, *n*-pentadecane, *n*-hexadecane, *n*-heptadecane, *n*-octadecane, and *n*-eicosane. The binary mixture *n*-decane/*n*-pentane we investigated at several different concentrations; all other mixtures were only investigated at a mass fraction of 50%. Even for the volatile *n*-pentane/*n*-decane mixture the deviations between the thermal diffusion coefficients determined by the different methods agreed within the error bars. Typically the agreement between the two methods was in the order of 5%. In comparison to recently published TC and TDFRS data we found deviations in the order of 30% up to 40%. We analyze and discuss the possible reasons for the discrepancies for the present and the past publications.

## I. Introduction

The coupling between a temperature gradient and a resulting mass flux is denoted thermal diffusion or the Ludwig–Soret effect in accordance with its discoverer and its first investigator. Particularly, the investigation of crude oil components such as alkanes and organic ring compounds is of practical relevance, because the determination of reliable model parameters is essential for the characterization of geological fields.<sup>1–3</sup> Additionally, the effect also plays an important role in separation techniques for liquid mixtures (see, e.g., refs 4–7).

In the simple case of a binary mixture with constant pressure there is a mass diffusion current  $j_D = -\rho D \nabla c$  and a thermal diffusion current  $j_T = -\rho D_T c(1 - c) \nabla T$ , with  $c$  the mass fraction,  $\rho$  the density of the liquid, and  $D$  and  $D_T$  the mutual mass and thermal diffusion coefficients, respectively. In the stationary state the two flows cancel, and the resulting concentration gradient is given by

$$\nabla c = -S_T c(1 - c) \nabla T \quad (1)$$

$S_T = D_T/D$  is the Soret coefficient.

The thermal diffusion of nonpolar fluid mixtures is sometimes governed by the mass, size, and shape of the molecules as well as their interactions (see ref 7 for a review). The influence of the physical parameters on the thermal diffusion behavior has been systematically investigated for isotopic mixtures of benzene and cyclohexane.<sup>8,9</sup> For these mixtures it was found that the Soret coefficient depends on the mass and moment of inertia difference but also on a chemical contribution. In the case of polar mixtures, specific interactions between the molecules dominate the thermal diffusion process, whereas mass and size are not so important.

A number of studies have focused on the Soret effect in mixtures containing an alkane as one of the components. Different experimental techniques were applied to investigate the thermal diffusion behavior of toluene/hexane,<sup>10–12</sup> alkane/alkane,<sup>13–15</sup> cyclohexane/benzene,<sup>8</sup> and *n*-alkane/benzene<sup>12,16–21</sup> mixtures. Also in a benchmark study of three binaries one of the components was an alkane.<sup>22</sup> In the past, thermodynamic models<sup>23</sup> have also been tested and simulations<sup>13</sup> have been performed for alkane mixtures.

Alkanes belong to the class of nonpolar mixtures. Often they are treated as ideal mixtures, because the minor microscopic effects, such as the conformational changes in the molecules, have only a very small effect on the usual thermodynamic properties of alkane/alkane mixtures. This tendency is also confirmed in a recent thermal diffusion study of alkane/alkane mixtures,<sup>14,15</sup> which shows that always the heavier component moves to the cold region. On the other hand minor microscopic effects contribute significantly to entropic and enthalpic thermodynamic properties.<sup>24</sup> Those deviations from ideality of linear alkanes are, for instance, also reflected in larger excess enthalpies compared to branched alkanes.<sup>25</sup> This might also be the reason for the observation that the heavier linear alkanes in equimolar mixtures of alkane/benzene mixtures tend to move to the warm side, whereas the highly branched alkanes accumulate at the cold side and show a more normal behavior.<sup>21</sup> If one uses the rule of the thumb that the denser component moves to the cold side the situation is reversed, because, for example, the density of heptane and its isomers is lower than the density of benzene, whereas the mass of benzene is larger than the mass of heptane. In order to complicate the situation even more 2,2,4-trimethylpentane, an isomer of octane, in benzene shows even a sign change with concentration.

We focus in this work on the Soret effect in binary alkane/alkane mixtures for which we expect a normal behavior. All mixtures are investigated by the thermogravitational column (TC) technique and thermal diffusion forced Rayleigh scattering (TDFRS) method. First we investigate the binary mixture

(b) Density of the same mixture as function of the column height at  $c = 0.5$  and  $T = 25$  °C. The results were obtained with the cylindrical TC. (c) Mass separation  $\Delta c$  for *n*-decane/*n*-pentane as function of the mass fraction of *n*-decane at  $T = 27$  °C.

*n*-decane/*n*-pentane at several different concentrations at 27 °C. This mixture we studied even with a cylindrical and parallel-epipedic thermogravitational column. The experimental data are compared with earlier experimental data and simulation results.<sup>13</sup> Additionally, we investigated binary mixtures of *n*-decane in *n*-hexane, *n*-heptane, *n*-octane, *n*-tetradecane, *n*-pentadecane, *n*-hexadecane, *n*-heptadecane, *n*-octadecane, and *n*-eicosane at a weight fraction of 50%. The obtained experimental data are also compared with recent measurements by the TC method.<sup>15</sup>

## II. Experimental Section

**II.A. Sample Preparation. II.A.1. Thermogravitational Columns.** All the products used in the TCs were purchased from Merck with a purity better than 99%. First we always filled in the less volatile component, i.e., the alkane with higher molecular weight; then the corresponding amount of the second alkane is added. The concentrations of the binary mixtures were adjusted by weighing both components separately. The mixtures for the parallelepipedic TC were prepared with a balance with a capacity up to 310 g and an accuracy of 0.0001 g. For the mixtures of the cylindrical TC we used a balance with a capacity up to 4500 g and an accuracy of 0.01 g. The sample volume needed to run an experiment in the parallelepipedic and cylindrical TC is approximately 25 and 300 cm<sup>3</sup>, respectively. As verification, before and after each experimental run the concentration of the mixture had been determined. The observed concentration change was typically in the order of  $\Delta c_0 = 0.0005$ .

**II.A.2. TDFRS.** The alkanes *n*-pentane ( $\geq 99\%$ ), *n*-hexane ( $\geq 99\%$ ), *n*-heptane ( $\geq 99.5\%$ ), *n*-octane ( $\geq 99.5\%$ ), *n*-octadecane ( $\geq 99\%$ ), and *n*-tetradecane ( $\geq 99\%$ ) were purchased from Fluka; *n*-decane ( $\geq 99\%$ ), *n*-heptadecane (99%), and *n*-eicosane (99%) were ordered from Aldrich. The alkane mole fraction of all mixtures was adjusted by weighing the components. The TDFRS experiments require a small amount of dye in the sample. In this work, all samples contained approximately 0.002 wt % of the dye quinizarin (Aldrich). This amount ensures a sufficient optical modulation of the grating but is small enough to avoid convection and contributions of the dye to the concentration signal. Before each TDFRS experiment, approximately 2 mL of the freshly prepared solution was filtered through a 0.2  $\mu$ m filter (hydrophobic PTFE) into an optical quartz cell with 0.2 mm optical path length (Helma) which was carefully cleaned from dust particles before usage.

After each measurement we checked carefully by monitoring the change of the meniscus height in the two filling capillaries of the sample cell whether the volatile solvent evaporated during the measurement. The accuracy of this method is certainly better than 1%. The total volume of the sample cell is in the order of

0.6 mL. Even for the *n*-decane/*n*-pentane mixture with the lowest pentane content, the concentration change should be less than  $\Delta x \approx \Delta c \approx 0.01$ .

**II.B. Data Analysis and Setup. II.B.1. Thermogravitational Columns.** The TC theory provides a relation between the stationary separation  $\Delta c$  and the thermodiffusion coefficient  $D_T$ . For more details see ref 26:

$$\Delta c = -\frac{504L_z D_T \nu}{gL_x^4 \alpha} c_0(1 - c_0) \quad (2)$$

where  $\alpha = -(1/\rho)(\partial\rho/\partial c)$  is the thermal expansion coefficient,  $\rho$  is the density of the mixture with the initial mass concentration  $c_0$ ,  $\nu$  is the kinematic viscosity, and  $g$  is the gravity acceleration.  $L_z$  is the height of the column, which is 500 mm for the cylindrical TC and 530 mm for the parallelepipedic TC. And  $L_x$  is the gap between the two vertical walls, which is  $1.000 \pm 0.005$  mm for the cylindrical TC and  $1.50 \pm 0.01$  mm for the parallelepipedic TC. Just taking into account the uncertainty in the gap dimension ( $L_x$ ) leads to a relative systematic error in the order of 2% and 2.7% for the cylindrical and parallelepipedic TC.

The mass separation between the two ends of the column  $\Delta c$  is determined from a calibration curve which relates mass fraction and density. In order to make the calibration, five mixtures with known concentration, close to the initial mass fraction ( $c_0 \pm 0.02$ ) are prepared by weighing. The accuracy of the determined mass is 0.0001 g. For the investigated mixtures we always obtained a linear relation between the density and the mass fraction. From the calibration curve the mass expansion coefficient  $\beta = (1/\rho)(\partial\rho/\partial c)$  is obtained. An example for the mixture *n*-decane/*n*-pentane is shown in Figure 1a.

We determine the stationary mass separation between the two ends of the column using the following expression:

$$\Delta c = \frac{L_z}{\beta \rho} \frac{\partial \rho}{\partial z} \quad (3)$$

where  $\partial\rho/\partial z$  is the vertical density gradient along the TC. The density gradient  $\partial\rho/\partial z$  is obtained from five samples which are equally distributed along the height of the TC. In all mixtures studied in this work the variation of the density with height is linear. A typical experimental result is shown in Figure 1b.

The stationary state is determined by the following expression:<sup>12</sup>

$$t_r = \frac{9!(L_z \nu)^2 D}{(g \pi \alpha \Delta T L_x^3)^2} \quad (4)$$

where  $t_r$  is the relaxation time and  $\Delta T$  is the applied temperature difference between the two vertical walls.  $\Delta T$  has been adjusted

<sup>a</sup> Chemical structure of the second component, mass fraction of *n*-decane, *c*, density,  $\rho$ , thermal expansion coefficient,  $\alpha$ , mass expansion coefficient,  $\beta$ , dynamic viscosity,  $\eta$ , refractive index increment with concentration  $(\partial n/\partial c)$  and temperature  $(\partial n/\partial T)$ .

to 6 °C, although in the stationary state the mass separation is independent of the applied temperature gradient.<sup>27</sup> Typically the time for reaching the stationary state is 5 times the relaxation time. We have repeated each measurement at least three times, and in one measurement we waited 15 times the relaxation time. All experimental results agreed with 2%, which indicates that the chosen time has been long enough to reach the stationary state.

Figure 1c shows the mass separation of the mixtures *n*-decane/*n*-pentane at different initial mass fractions. The separation  $\Delta c$  shows a maximum at a mass fraction of *n*-decane at *c* = 0.6.

**II.B.2. TDFRS.** The thermal diffusion behavior of the solutions was investigated by TDFRS. A detailed description of the setup can be found elsewhere.<sup>28</sup>

The heterodyne diffraction signal  $\zeta_{\text{het}}$  is evaluated by the equation

$$\zeta_{\text{het}}(t) = 1 + \left(\frac{\partial n}{\partial T}\right)^{-1} \left(\frac{\partial n}{\partial c}\right) S_T c(1-c)(1 - e^{-q^2 D t}) \quad (5)$$

with the refractive index increment with concentration at constant pressure and temperature  $(\partial n/\partial c)$ , the derivative of the refractive index with temperature at constant pressure and concentration  $(\partial n/\partial T)$ , and the collective diffusion coefficient *D*.

**II.C. Density Measurements.** The thermal expansion  $\alpha$ , the mass expansion  $\beta$ , and the density  $\rho$  of all the mixtures have been measured with an Anton Paar DMA 5000 vibrating quartz U-tube densimeter. It has a reproducibility of  $1 \times 10^{-6} \text{ g/cm}^3$  with a temperature accuracy of 0.001 °C. The sample volume needed to make one density measurement is roughly 1.5 mL. The thermophysical properties of all the mixtures studied in this work are shown in Table 1.

**II.D. Viscosity Measurements.** The dynamic viscosity has been determined by a HAAKE falling ball viscosimeter with an estimated accuracy of  $\pm 1\%$ . The temperature stability is  $\pm 0.1$  °C. The volume needed to make one viscosity measurement is approximately 40 mL. The dynamic viscosities  $\eta$  listed in Table 1 are the average of at least eight individual measurements with typical standard deviation (SD) below 1%.

**II.E. Refractive Index Increments.** An Anton Paar RXA 156 refractometer has been used to measure the refractive index

increments with the mass concentration  $(\partial n/\partial c)$  (see Table 1). It has a repeatability of  $2 \times 10^{-5}$ , and the temperature accuracy is  $\pm 0.01$  °C. The volume needed to make one measurement is less than 1 mL. For all investigated temperatures and concentrations we find a linear dependence of the refractive index on concentration if the temperature is fixed or on temperature if the concentration is fixed. For all mixtures we determined the  $(\partial n/\partial c)$  values. We would like to point out that the refractive index increments with concentration, which had been determined for the mixture *n*-decane/*n*-pentane in the previous work<sup>13</sup> by an Abbe refractometer, agreed with the new values within the error bars.

The TDFRS measurements for all mixtures except for the system *n*-decane/*n*-pentane  $(\partial n/\partial T)$  were directly measured by an interferometer. In the case of *n*-decane/*n*-pentane  $(\partial n/\partial T)$  the reliability of the refractometer was better, because due to the long measurement time in the interferometer pentane evaporated partly, which led to concentration changes during the measurement. The contrast factors  $(\partial n/\partial c)$  and  $(\partial n/\partial T)$  for two groups of mixtures are listed in Table 1.

### III. Results and Discussion

**III.A. Thermal Diffusion Behavior of *n*-Decane in *n*-Pentane.** Figure 2 shows the thermal diffusion coefficient  $D_T$  for *n*-decane in *n*-pentane for several mass fractions of *n*-decane. In general  $D_T$  decays with increasing *n*-decane content. The measurements between the parallelepipedic and cylindrical thermogravitational columns agree typically better than 5%. We estimated the error bars for the TC by error propagation taking into account the experimental uncertainties of the auxiliary quantities such as viscosity ( $<1\%$ ), mass expansion ( $<1\%$ ), thermal expansion ( $<0.5\%$ ), variation of the density with height in the column (typically better than 2% and 3% for cylindrical and parallelepipedic TCs, respectively), and geometrical parameters (typically better than 1% and 3% for cylindrical and parallelepipedic TCs). The error bars for the TDFRS data correspond to 1 SD of the mean for repeated measurements. The actual TDFRS data are systematically 5–11% higher than the TC data but agree within the error bars. The highest deviation in comparison with the TDFRS data of 11% has been found for the lowest pentane content. This concentration is the one

**Figure 2.** Thermal diffusion coefficient  $D_T$  for  $n$ -decane in  $n$ -pentane in dependence of the mass fraction of  $n$ -decane obtained by a parallelepipedic TC ( $\nabla$ ), cylindrical TC ( $\Delta$ ), and TDFRS ( $\square$ ). For comparison we also show the previous experimental ( $\circ$ ) and simulation results in the center-of-volume reference frame ( $\bullet$ ) (ref 13).

which is most sensitive to the evaporation of pentane. The same absolute loss of pentane leads for this concentration to a much larger relative concentration change compared to concentrations with a higher pentane content. In both experiments a potential loss of pentane was carefully monitored as described in sections II.A.1 and II.A.2, respectively. The expected changes in concentration are smaller than the symbol size.

In addition, the thermal diffusion coefficient of  $n$ -decane in  $n$ -pentane mixtures for different concentrations deviates less than 3% from the values obtained with another cylindrical column,<sup>29</sup> which is an independent measurement by another group.

The old TDFRS measurements<sup>13</sup> are systematically 10–20% lower than the present TDFRS data, and the deviation with the TC data are in the order of 5–15%. The deviations between the two sets of TDFRS data can probably be explained by the fact that at that time the data had not been corrected by the so-called excitation function which accounts for time delays in the electrical switching of the Pockels cell. A detailed description of the procedure can be found in ref 28.

We also compare our new TC and TDFRS data with previous nonequilibrium molecular dynamic simulation results for the system  $n$ -decane/ $n$ -pentane by Perronace et al.<sup>13</sup> (see Table 2). The simulations have been carried out in the center-of-mass reference frame, and the resulting transport coefficients have been transformed to the center-of-volume reference frame, which corresponds to the situation in the experiment. The statistical uncertainty of the simulations is in the order of 35%, whereas the systematic deviations between experimental and simulation data are in the order of 15–40%. For instance, for the equimolar mixture  $n$ -decane/ $n$ -pentane the data agree almost within the error bars.

**III.B. Thermal Diffusion Behavior of  $n$ -Decane in Various Alkanes at Equal Mass Ratio.** Additionally we performed measurements for  $n$ -decane with various shorter and longer

linear alkanes. The thermal diffusion and diffusion coefficients for  $n$ -decane in various alkanes with a mass fraction of 50% at  $T = 25^\circ\text{C}$  are listed in Table 3. For comparison we also list previous thermal diffusion data, which have also been obtained by a parallelepipedic TC but with different dimensions.<sup>15</sup> The diffusion coefficients from the same reference<sup>15</sup> have been determined by the open-end capillary (OEC) method.<sup>30</sup>

Figure 3a shows the thermal diffusion, mutual diffusion, and Soret coefficients for the measurement with the cylindrical TC and the TDFRS setup as function of the molar mass of the second component. For comparison we also show the previous data by Leahy-Dios and Firoozabadi.<sup>15</sup> As expected, the thermal diffusion coefficient of  $n$ -decane in shorter alkanes is positive, and therefore the  $n$ -decane goes toward the cold region, whereas it becomes negative when the mass of the second component becomes larger, which implies that  $n$ -decane migrates to the warm side. The agreement between the cylindrical TC and the TDFRS data is typically better than 5%.

If we compare our data with recent data in the literature,<sup>15</sup> we find deviations between 10–30%. In comparison to those previous measurements the TC used in this work allows a more accurate analysis of the mass separation between the top and the bottom of the TC due to the smaller gap and a better precision of the gap of  $L_x = 1.0 \pm 0.005$  mm (cf., section II.B.1). The TC used by Leahy-Dios and Firoozabadi<sup>13</sup> had a gap of  $1.6 \pm 0.02$  mm. This low precision of the gap dimensions causes an uncertainty of  $\pm 5\%$  in the determination of the thermal diffusion coefficient, not regarding the propagating errors due to uncertainties in the thermophysical properties, which are required to calculate the thermal diffusion coefficient (see eqs 2 and 3). For the TC used in this work the mass separation is 6.55 times greater than for the TC used in ref 15. Therefore, the difference in the thermal diffusion coefficient,  $D_T$ , determined with those two columns (ref 15 and this work) becomes larger for mixtures with a small mass separation. This tendency can be observed for the mixtures  $n$ -decane/ $n$ -heptane and  $n$ -decane/ $n$ -hexadecane. In contrast to the previous measurements we could not confirm the nonmonotonic trend of the thermal diffusion coefficient with increasing molecular weight of the second component. Both measurement techniques, TC and TDFRS, indicate that  $D_T$  becomes constant and therefore independent of the molecular weight of the second component. This is also the behavior which has been observed for infinite diluted solutions of polymers.<sup>31,32</sup>

Figure 3b shows a comparison between the diffusion coefficients determined in the previous study by the OEC technique and the present TDFRS study. In general, the OEC data are systematically lower than for the TDFRS data. Typically one finds deviations larger than 30% in the entire molar mass range of the second compound. Typically the agreement is better for

<sup>a</sup> In the first two columns the totals formula and the molecular weight of the second component are listed.  $D_T^{\text{TC}}$  and  $D^{\text{OEC}}$  refer to previous experimental data (ref 15).  $D_T^{\text{TC}}$  and  $D_T^{\text{TDFRS}}$  have been measured in this work by cylindrical TC and TDFRS. Details are given in the text.  
<sup>b</sup> Ref 15.

**Figure 3.** Thermal diffusion coefficient  $D_T$ , diffusion coefficient  $D$ , and Soret coefficient  $S_T$  for *n*-decane in different alkanes in dependence of the molar mass of the second alkane component measured by TC ( $\Delta$ ) and TDFRS ( $\square$ ). For comparison we also show the data ( $\circ$ ) obtained in the previous work by Leahy-Dios and Firoozabadi (ref 15). All measurements have been performed for  $c = 0.5$  at a temperature  $T = 25^\circ\text{C}$ .

the higher molar mass components than the lower molecular weight components; therefore, evaporation problems might be responsible for these discrepancies.

In Figure 3c we compare the Soret coefficients determined by the TDFRS method with the previous results by Leahy-Dios and Firoozabadi.<sup>15</sup> Both studies show a decay of the Soret coefficient with increasing molecular weight of the second component. Although the previous data seem to show a vague minimum, our data do not confirm this trend. The magnitude of the Soret coefficient calculated<sup>15</sup> from the thermal diffusion coefficient determined by the TC method and diffusion coefficients measured with the OEC method is always larger than the  $S_T$  values determined in the TDFRS experiment. The deviations are typically in the order of 20–40%.

#### IV. Conclusion

In this paper, we systematically studied binary alkane mixtures by two different techniques: a convective method, the TC (parallelepipedic and cylindrical configurations) technique, and a nonconvective method, TDFRS. In general we found a very good agreement between these two methods. Nevertheless we found some discrepancies with data published in the literature. The observed disagreement between the published TDFRS<sup>13</sup> data for the mixture *n*-decane/*n*-pentane is probably caused by an improved data analysis algorithm, which accounts for finite rising times and slow drifts of the electro-optic devices used in the experiment. Additionally, we found discrepancies with recently published TC data.<sup>15</sup> We assume that the reason for the disagreement of the recent TC data is the larger gap  $L_x$  in the previously used cell<sup>15</sup> compared to the cells used in this work. The larger gap decreases the accuracy of determining the mass separation between the two ends of the TC. This is especially important for the mixtures of decane with the higher alkanes. Neither our TC nor our TDFRS measurements showed the upward trend of the thermal diffusion coefficient,  $D_T$ , for the higher alkanes, which was recently observed.<sup>15</sup> Our measurements seem to indicate that the thermal diffusion coefficient becomes independent of the molar mass of the second component. This issue could certainly be further investigated by molecular simulations as has been done for alkane mixtures and other small molecules.<sup>13,33</sup>

**Acknowledgment.** The authors thank Dr. Hartmut Kriegs for his experimental assistance, Professor J. K. Platten for yielding us the parallelepipedic TC of the University of Mons, and Professors J. A. Madariaga and C. Santamaría for the discussion of the experimental results in the mixtures of *n*-pentane and *n*-decane. This work was partially supported by the Deutsche Forschungsgemeinschaft Grant Wi 1684, the Basque Government Grant BFI05.449, and the projects GOVSORET (PI2008-14) and TES-BLUR (CTQ2005/09389/C02/01/PPQ).
