Received: June 1, 2006; In Final Form: December 8, 2006

Raman scattering and Fourier-transform infrared (FT-IR) attenuated transmission reflectance (ATR) spectra of two α -amino acids (α -AAs), i.e., glycine and leucine, were measured in H₂O and D₂O (at neutral pH and pD). This series of observed vibrational data gave us the opportunity to analyze vibrational features of both AAs in hydrated media by density functional theory (DFT) calculations at the B3LYP/6-31++G* level. Harmonic vibrational modes calculated after geometry optimization on the clusters containing each AA and 12 surrounding water molecules, which represent primary models for hydration scheme of amino acids, allowed us to assign the main observed peaks.

I. Introduction

The behavior of amino acids (AAs) in aqueous solutions is of a major interest because water is the natural medium for biological molecules. A detailed knowledge of AA interactions with water is a primary step in understanding the solvation process of larger systems, such as peptides and proteins. Hydrophilic or hydrophobic feature of the side chain (R) also plays an important role in the hydration process of a given amino acid. Geometric and hydration analyses of glycine (G), considered as a prototype for larger AAs in both neutral and zwitterionic forms, have received considerable attention. Experimentally, in the context of mass spectrometric and sizeselected photoelectron spectroscopic studies, it has been shown that five water molecules are needed to transform neutral glycine into its zwitterion.1 Theoretically, one can recall here the first report presented by Clementi's group² in which an amino acid and a water molecule (W) were treated separately at the SCF level of theory, whereas their mutual interaction was considered by the use of a classical Buckingham potential. Since 10 years ago, a series of ab initio calculations have been devoted to the estimation of the relative stability of glycine conformers in gas and hydrated phases.3-14 One of these reports considers the glycine environment (including water) as a dielectric continuum characterized by its macroscopic permittivity. 9 In other reports, HF, DFT/B3LYP and MP2 methods have been applied to study the complexation of glycine with one water (referred to as G+1W) cluster molecule placed differently around this amino acid.^{7,10-11} The whole geometry was optimized by means of different Gaussian basis sets and the relative stability of 1:1 complex (G+1W) configurations was estimated. It was concluded that the geometrical data obtained at the DFT and MP2

levels are more reliable than those estimated at the HF level even when extended basis sets are used. Zwitterionic form of

the G+1W cluster was shown to be unstable, and the geometry

optimization tends in all cases toward a neutral form of G.

Moreover, the vibrational wavenumbers calculated at the DFT

level on an isolated G (neutral form) have been compared with

those observed in the gas phase without the use of any scaling factor thanks to a good agreement between experimental and theoretical data. 11 A systematic theoretical analysis at the DFT/ B3LYP/6-31++G** level supported by experimental matrixisolation FT-IR results,12 pointed to the necessity of at least two water molecules to maintain the zwitterionic form, thus avoiding the proton transfer from NH₃⁺ to COO⁻ group upon geometry optimization. However, the zwitterionic G+2W and G+3W were found to be less stable than neutral forms of the same complexes. For G+4W and G+5W complexes, the higher stability of the zwitterionic forms was proved. We must emphasize two recent systematic theoretical works devoted to the tautomerization (zwitterionic → neutral form) of isolated and hydrated G.13-14 Different clusters containing a number of water molecules varying from one to six were considered in the mentioned calculations performed at the DFT/B3LYP level with the basis sets equipped with diffuse functions at least on heavy atoms. It has been again confirmed, as reported in other works (see above), that the neutral species exist in the gas phase as well as in mono- and dihydrated clusters, whereas for a larger number of water molecules, the zwitterionic form is better solvated than the neutral one. Thus, the zwitterion to neutral tautomerization becomes less exothermic for clusters containing up to three water molecules and endothermic for larger clusters, and the neutral form does not exist for some solvent arrangements with five water molecules. In addition to all theoretical reports mentioned above, which have given a static picture of hydrated glycine and its proton-transfer mediated or not by water molecules, a recent work has proposed a very interesting

Figure 1. Chemical structures of glycine (left) and leucine (right).

dynamic representation of these aspects by means of a combined use of QM/MM and ab initio Car-Parrinello molecular dynamics (CPMD).15 Fundamental questions have been addressed through the results obtained over a 10-20 ps dynamics, such as (i) energy barriers for proton transfer, (ii) time-dependent hydration numbers on COO⁻ and NH3⁺ groups, and (iii) paircorrelation functions between the oxygen, nitrogen and hydrogen atoms of glycine and hydrogen atoms on water molecules. As far as the G hydration is concerned, the conclusion of this extensive work was that 4.7 water molecules are bound in average to COO⁻ group, whereas 3.0 hydrogen bonds are predicted between the NH₃⁺ group and water molecules. Despite the above-mentioned careful analyses on G hydration, a theoretical investigation of its vibrational properties in hydrated media is still lacking in the literature. This is also the case for most of the AAs. The only data available on the assignment of AA vibrational modes (and those arising from side chains: 1400-1200 cm⁻¹ region) are based on the isotopic shifts observed in aqueous solution Raman spectra of native and deuterated species (deuteration on C_{α} as well as on the carbons of their side chains) in some AAs with nonaromatic and aromatic side chains.16-18

The present work reports the first part of a series of our investigations devoted to the analysis of vibrational properties of amino acids and short peptides in hydrated media. Here, our attention is basically focused on the vibrational features of two AAs: glycine (G) with R = H, the structurally simplest AA, and leucine (L) with a large size hydrophobic side chain, R = CH₂-CH-(CH₃)₂ (Figure 1). From the experimental point of view, we present newly recorded Raman spectra of both AAs complimented by their FT-IR spectra recorded in H₂O and D₂O. In order to propose theoretical results based on the models which permit comparison with experiments, we have undertaken vibrational calculations at the DFT/B3LYP level on the clusters containing 12 water molecules mimicking reasonably the hydration scheme in the vicinity of glycine and leucine backbone.

II. Experimental Details

Powder samples of the AAs were purchased from Calbochem and Sigma-Aldrich and used as provided. Solutions of both AAs were prepared by dissolving each compound in phosphate buffer, pH (pD) = 6.8, containing 10 mM monovalent cations (Na⁺ and K⁺) and 1 mM EDTA, to obtain aqueous samples of 50 mM molecular concentration used for Raman spectroscopy. FT-IR (ATR) spectra were obtained from solutions of AAs (c =100 mM) prepared directly in H₂O or D₂O. Raman spectra were excited at 488 nm with an Ar+ laser (Stabilite model 2017-

04S, Spectra Physics) and collected on a Jobin-Yvon T64000 spectrograph in a single spectrograph configuration with a 1200 grooves/mm holographic grating and a holographic notch filter. The spectrograph is equipped with a liquid nitrogen cooled CCD detection system (Spectrum One, Jobin-Yvon) based on a Tektronix CCD chip of 2000×800 pixels. The effective spectral slit width was set to ca. 5 cm⁻¹. Raman spectra were collected at room temperature. ATR spectra of AAs were recorded at room temperature with a FT-IR Perkin-Elmer 2000 spectrophotometer equipped with an ATR accessory, under continuous dry air purge. Solutions in D₂O (>99.8%) purity, purchased from Euriso-Top CEA), were prepared under dry air atmosphere. Typically 18 μ L of sample solutions were deposed in drops on the ZnSe crystal of the ATR accessory, and spread to cover the whole surface. Infrared beam, with an effective angle of incidence of 45°, follows 12 reflections from the entrance to the exit points in the ATR crystal. The effective path length (number of reflections × depth of penetration, dp) was around 15 micrometers, where dp is calculated as follows: dp = (λ) $/n_c$)/ $(2\pi[\sin^2\theta - (n_s/n_c)^2]^{1/2}$), where λ = wavelength (mm), n_c = refractive index of crystal, n_s = refractive index of sample, θ = crystal face angle (degrees). Usually 20 scans were collected with 1 cm⁻¹ spectral resolution and a medium Norton Beer apodization function. Postprocessing (subtraction of buffer contribution, baseline correction and smoothing) of Raman spectra was performed using GRAMS/32 software (Galactic Industries). ATR data treatment was performed using the Perkin-Elmer Spectrum program and consisted only in solvent subtraction and multiple-point baseline correction. Final presentation of vibrational spectra shown in this paper has been performed by means of SIGMAPLOT package.

III. Theoretical Details

To analyze the geometrical and vibrational features of AAs with their surrounding water molecules, the DFT method has been adopted because of its excellent compromise between computational cost and involvement of electronic correlation. All quantum mechanical computations have been performed on the IBM workstations using the GAUSSIAN03 package.¹⁹ B3LYP functional, with Becke's three parameter (B3) exchange functional,²⁰ along with the Lee-Yang-Parr (LYP) non local correlation functional, 21 were used. Split valence double- ζ gaussian atomic basis sets containing diffuse functions on both heavy and hydrogen atoms, i.e., 6-31++G*, were employed in order to give a static picture of zwitterionic character of amino acids in aqueous medium by taking into account the results obtained by previous static DFT calculations on penta- and hexahydrated glycine,14 as well as those of recent CPMD calculations. 15 To achieve this objective, geometry optimization was first carried out on a simple model G+3W. As shown in previous works, 11-14 the presence of three water molecules, placed between COO⁻ and NH₃⁺ chemical groups and forming intermolecular H-bonds: W···W and W···AA, is absolutely necessary to avoid proton transfer between the two charged sides of G. In further steps, we have considered a total number of 12 water molecules in order to fully hydrate COO- (4 W) and NH3⁺ groups (3 W) and to create a reasonable hydrogen bond network between their hydration shells. Optimized structure of G+12W was considered as a starting point for modeling hydrated leucine. We have replaced the glycine side chain by that of leucine (Figure 1). No additional water molecule was placed around the L side chain because of its hydrophobic character. The whole cluster L+12W was then geometry optimized. No correction due to the basis set superposition error

Figure 2. Vibrational spectra of glycine observed in aqueous solutions. From top to bottom: Raman spectrum recorded in H_2O buffer ($\lambda_L = 488$ nm), FT–IR ATR spectrum recorded in H_2O buffer, Raman spectrum recorded in D_2O ($\lambda_L = 488$ nm), FT–IR ATR spectrum recorded in D_2O . The intensity of each observed spectrum was normalized to the most intense peak in order to facilitate their comparison.

(BSSE) was considered in the course of quantum mechanical calculations. As shown in our previous calculations on hydrated uracil at the same level of theory the BSSE correction brings only a negligible change to electronic energy.²² Harmonic vibrational calculations performed after full geometry optimization provided no imaginary frequency, leading to conclude that G+12W and L+12W optimized geometries correspond well to local energy minima. Hessian matrix containing cartesian force constants, output from the Gaussian package, was posttreated by means of a homemade program (BORNS) allowing us to remove redundancies among vibrational coordinates and to assign wavenumbers on the basis of the PED (potential energy distribution) matrix elements as expressed in terms of a combination of local symmetry and internal coordinates (atomic cartesian coordinates of the optimized geometries, cartesian force constants and assignments of all calculated wavenumbers are available upon request). Local symmetry coordinates are those generally defined in the case of perfect C_{2v} and C_{3v} point groups; they reflect the symmetric or antisymmetric character of corresponding vibrations. However, we are conscious that the local C_{2v} (for COO⁻ and CH₂) or C_{3v} (NH₃⁺ and CH₃) symmetries are lowered when the corresponding chemical groups are introduced in the backbone or the side chain of AAs.

Figure 3. Vibrational spectra of leucine observed in aqueous solutions. From top to bottom: Raman spectrum recorded in H₂O buffer ($\lambda_L = 488$ nm), FT–IR ATR spectrum recorded in H₂O buffer, Raman spectrum recorded in D₂O ($\lambda_L = 488$ nm), FT–IR ATR spectrum recorded in D₂O. The intensity of each observed spectrum was normalized to the most intense peak in order to facilitate their comparison.

Figure 4. Stereoviews of G+12W (top) and L+12W (bottom) supermolecules. Geometry optimization was performed at the DFT/B3LYP/6-31++G* level of theory. Water molecules are numbered from 1 to 12 on the left part of each Figure.

The whole AA (with or without its surrounding water molecules) possesses evidently a global C₁ symmetry. This explains the

 a s. intense, m. medium, w. weak, sh. shoulder. Raman: vibrational wavenumbers in Raman spectra recorded in H₂O and D₂O buffers (Figure 2). IR: vibrational wavenumbers observed in FT–IR ATR spectra recorded in H₂O and D₂O (Figure 2). Calc: calculated results obtained at DFT/B3LYP/6-31++G* the level on a theoretical model including glycine surrounded by 12 water molecules (Figure 4). Only major contributions (PED \geq 8%) are reported in this Table. Assignments of the vibrational modes are based on the potential energy distribution (PED) based on internal coordinates. In front of each internal coordinate is reported the corresponding PED (in percent).

comparison between observed wavenumbers and "raw" calculated ones in order to evidence the defaults of both the theoretical level (even though it is adequately chosen in the present work) and the harmonic approximation. The assignment of vibrational modes was undertaken by considering mainly their isotopic shifts. Particularly in the case of leucine, we have taken into consideration the assignments based on the vibrational spectra of alanine, ^{23–26} valine, ²⁷ and leucine, ¹⁶ i.e., three amino acids with nonaromatic side chains.

IV. Results

Raman and FT-IR ATR Spectra. The observed vibrational spectra of glycine and leucine are displayed in Figures 2 and 3, respectively. In each Figure, we report the Raman and FT-IR spectra recorded in H_2O and D_2O buffers, each one normalized to its most intense band. The peak positions and spectral shape of Raman spectra in H_2O are very close to those reported previously.²³ In Tables 2 and 3 the wavenumbers and the relative

intensities of the main peaks observed in each spectrum, are listed. Spectra recorded in D_2O buffer clearly show the effect of $NH_3^+ \rightarrow ND_3^+$, i.e., labile hydrogen deuteration, on the vibrational modes of each AA.

Theoretical Results. Stereoviews of optimized G+12W and L+12W clusters are shown in Figure 4, along with the numbering of water molecules. As it can be seen, among the twelve surrounding water molecules, eight are located at one side and the other four at the other side of the backbone of each amino acid. Six of the eight water molecules are located approximately in an average plane (W3, W4, W5, W7, W8, W10), at the same side of the backbone. Based on the present calculations, eight of the 12 water molecules are located undoubtedly in the first hydration shells of the backbone of each AA. The other four water molecules belong to the second shell of hydration (W1, W3, W5, W11), making intermolecular H-bonds with the water molecules of the first hydration shell. Table 1 shows the values of electronic (*E*_e) and vibrational

 $[^]a$ s. intense, m. medium, w. weak, sh. shoulder. Raman: vibrational wavenumbers in Raman spectra recorded in H₂O and D₂O buffers (see Figure 3). IR.: vibrational wavenumbers observed in FT–IR ATR spectra recorded in H₂O and D₂O (Figure 3). Calc: calculated results obtained at DFT/B3LYP/6-31++G* the level on a theoretical model including leucine surrounded by 12 water molecules (Figure 4). Only major contributions (PED \geq 8%) are reported in this Table. Assignments are based on the potential energy distribution (PED). In front of each internal coordinate is reported the corresponding PED (in percent).

energies ($E_{\rm v}=1/2~\Sigma h\nu$, where h is the Plank constant and ν the frequency of a vibrational mode) for each supermolecule. In the same table are the main geometrical parameters, such as bond length and valence angles for AAs as well as for water molecules, and additionally, the H-bond lengths related to the water molecules interacting with the NH₃⁺ and COO⁻ charged groups of each AA. The calculated vibrational wavenumbers located in the $1800-700~{\rm cm}^{-1}$ spectral range, arising mainly from amino acids, are reported in Tables 2 and 3 for comparison with the observed Raman and IR peaks.

V. Discussion

As Table 1 shows, the change in the chemical structure of the side chains only affects the geometrical parameters (bond lengths and valence angles) of atoms located in the vicinity of C_α . In addition, this change does not considerably perturb the whole H-bond network structure (W···W and W···AA) around AAs. This is principally due to the fact that all water molecules were basically located around the backbone of AAs, and also to the hydrophobic character (not hydrated) of the L side chain. On the basis of the present calculations, it can also be confirmed that the geometrical parameters of water molecules (bond lengths and valence angles) are not considerably affected by the chemical composition of the two studied amino acids. From the vibrational point of view, the comparison between the observed and calculated results can be undertaken through three spectral regions, as follows:

1750–1500 cm⁻¹ Spectral Region. Thanks to the existence of intense IR bands, the vibrational modes arising from NH₃⁺ angular bending and COO⁻ out-of-phase stretching motions can be appreciated (Tables 2 and 3). NH₃⁺ bending modes observed at ca. 1640 cm⁻¹ and 1510 cm⁻¹ in IR spectrum completely disappear upon H–D isotopic substitution. Moreover, the calculations show that the NH₃⁺ bending modes are considerably coupled with those of surrounding water molecules through W...AA hydrogen bonds. The same consideration explains that the COO⁻ asymmetric stretching mode observed at ca. 1600 cm⁻¹ in both AAs in H₂O buffer, is shifted to higher wavenumbers in heavy water and give rise to intense and narrow IR bands at ca. 1615 cm⁻¹ (Figures 2 and 3).

1500–1200 cm⁻¹ **Spectral Region.** Both Raman and IR spectra give rise to intense bands in this region. Apart vibrational modes arising from COO⁻ in-phase stretching and NH₃⁺ angular bending motions, this region provides very useful information on the side chain vibrational modes of CH₂ and CH₃ groups in leucine. The calculations allow us to assign the leucine modes observed in the 1450–1300 cm⁻¹ spectral region to the HCH and CCH angular bendings, centered on the C $_{\beta}$, C $_{\gamma}$, C $_{\delta 1}$, and C $_{\delta 2}$ atoms of its side chain (Table 3), showing small isotopic shifts upon deuteration.

Below 1200 cm⁻¹. In this spectral region, deuteration leads somehow to a rearrangement of the vibrational modes (from skeletal origin in G, mainly from the side chain in L). The main vibrational modes of glycine are observed at 1033 and 898 cm⁻¹ (Figure 2) are both assigned to the vibrational motions located around C_α atom. Both of them are considerably affected by deuteration (1033 \rightarrow 1001 cm⁻¹; 898 \rightarrow 837 cm⁻¹) because of the H–D replacement in the NH₃⁺ group in one hand, and of the tight interaction of the COO⁻ group with its surrounding water (heavy water) molecules. An interesting effect in this region is the emergence of an intense mode at 966 cm⁻¹ in Raman spectrum of deuterated glycine (Figure 2). This fact is interpreted by the coupling of the COO⁻ symmetric stretch motion with those corresponding to the C–C_α and N–C_α bonds.

Like in the previous spectral region (1500–1200 cm⁻¹), leucine presents here a more complex vibrational scheme in comparison with glycine (Figure 3). The reason behind this fact can be explained as before: the more complex structure of the leucine side chain compared to that of glycine. The presence of explicit solvent around amino acids in the theoretical model considered in the present work allows us to appreciate, in many cases (Tables 2 and 3), the contribution of water molecules to the observed vibrational modes. Particularly, we can notice the modes with low intensity observed at 997 and 980 cm⁻¹ in the Raman spectrum of glycine (Figure 2) which are mainly assigned to the intermolecular motions of W···AA and W···W types.

In conclusion, the present calculations lead us to conclude that terminal NH3⁺ and COO⁻ groups of both amino acids might be, *in average*, fully hydrated in aqueous solution. This conclusion confirms the results obtained theoretically by recent CPMD calculations on hydrated glycine.²⁴

VI. Concluding Remarks

This report presents a complete series of experimental results on vibrational features of glycine and leucine. As the side chain of both amino acids contain nonexchangeable hydrogens upon deuteration in heavy water, all isotopic shifts observed in vibrational spectra should mainly arise from the H-D substitution at the N-terminal of AAs and their interaction with surrounding heavy water. To propose reasonable assignments to the observed vibrational spectra, quantum mechanical calculations at the DFT/B3LYP/6-31++G* level of theory were performed on a cluster containing 12 water molecules surrounding the backbone of each amino acid. However, we are conscious that the calculated results based on the resolution of the time-independent Schrödinger equation, give only a static picture of hydration with fixed water molecules H-bonded to amino acids. The present models should thus be considered as a first step in investigating the dynamic hydration scheme of AAs in hydrated media. Acceptable assignments for vibrational spectra, along with reasonable isotopic shifts upon deuteration lead us now to consider quantum mechanical dynamics calculations on the hydrated AAs and peptides.

Acknowledgment. This work was performed thanks to a cooperation involving the Laboratoire de Spectroscopie Atomique Moléculaire et Applications (LASMA, Faculty of Science, EL MANAR University, Tunisia), the Department of Physics (University of Ngaoundere, Cameroon), and the Laboratoire de Biophysique Moléculaire, Cellulaire and Tissulaire (BioMoceTi, University Paris 13, France). We thank the Agence Universitaire pour la Francophonie (AUF) for the financial support to the scientific project (ref 6313PS567) established for a 2 year period 2005–2006, encouraging the mobility of Tunisian, Cameroonian, and French researchers. We also acknowledge two French supercomputer centers: IDRIS (Orsay, France) and CINES (Montpellier, France) for the computational time allocated to this project on IBM workstation networks.
